

Q.1. What is the use of search in regular expression explain with example?

The **search()** function is available in Python's **re (Regular Expression)** module. It is used to **search for a specific pattern anywhere in a string**.

Unlike some other regular expression functions, **search()** does not require the pattern to be at the beginning of the string. It checks the string from beginning to end and returns the **first match** it finds.

Syntax

```
re.search(pattern, string)
```

Example 1: Searching for a word

```
import re
text = "I am learning Python programming."
result = re.search("Python", text)
if result:
    print("Python found in the string")
else:
    print("Python not found")
```

Output:

Python found in the string

Example 2: Searching for a number

```
import re
text = "My age is 21 years."
result = re.search(r"\d+", text)
```

```
if result:
```

```
    print("Number found:", result.group())  
else:  
    print("Number not found")
```

Output:

Number found: 21
